Abstract

It appears difficult to construct a simple model for an open universe based on the one bubble inflationary scenario. The reason is that one needs a large mass to avoid the tunneling via the Hawking Moss solution and a small mass for successful slow-rolling. However, Rubakov and Sibiryakov suggest that the Hawking Moss solution is not a solution for the false vacuum decay process because it does not satisfy the boundary condition. Hence, we have reconsidered the arguments for the defect of the simple polynomial model. We point out the possibility that one of the valley bounce belonging to a valley line in the functional space represents the decay process instead of the Hawking Moss solution. Under this presumption, we show an open inflation model can be constructed within the polynomial form of the potential so that the fluctuations can be reconciled with the observations.

1 Introduction

Recent observations suggest the matter density of the universe is less than the critical density. Hence, it is desirable to have a model for an open universe, say $\Omega_0 \sim 0.3$. The realization of an open universe is difficult in the ordinary inflationary scenario. This is because if the universe expands enough to solve the horizon problem, the universe becomes almost flat. One attempt to realize an open universe in the inflationary scenario is to consider inside the bubble created by the false vacuum decay [1]. The scenario is as follows. Consider the potential which has two minimum. One is the false vacuum which has non-zero energy and the other is the true vacuum. Initially the field is trapped at the false vacuum. Due to the potential energy, universe expands exponentially and the large fraction of the universe becomes homogeneous. As the false vacuum is unstable, it decays and creates the bubble of the true vacuum. If the decay process is well suppressed, the interior of the bubble is still homogeneous. The decay is described by the $O(4)$ symmetric configuration in the Euclidean spacetime. Then, analytical continuation of this configuration to the Lorentzian spacetime describes the evolution of the bubble which looks from the inside like an open universe. Unfortunately, since the bubble radius cannot be greater than the Hubble radius, the created universe is curvature dominated even if the whole energy of the false vacuum is converted to the energy of the matter inside the bubble [2]. Thus, the second inflation in the bubble is needed. If this second inflation stopped when $\Omega < 1$, our universe becomes homogeneous open universe.

Though the basic idea is simple, the realization of the scenario in a simple model has been recognized difficult [3]. The difficulty is usually explained as follows. Consider the model involving one scalar field. For the polynomial form of the potential like $V(\phi) = m^2\phi^2 - \delta\phi^3 + \lambda\phi^4$, the tunneling should occur at sufficiently large ϕ to ensure that the second inflation gives the appropriate density parameter. Then, the curvature around the barrier which separates the false and the true vacuum is small compared with the Hubble scale which is determined by the energy of the false vacuum. The field jumps up onto the top of the barrier due to the quantum diffusion. When the field begins to roll down from the top of the barrier, large fluctuations are formed due to the quantum diffusion at the top of the barrier. Then the whole scenario fails. The problem is rather generic. To avoid jumping up, the curvature around the barrier should be large compared with the Hubble scale $V'' > H^2$. On the other hand, to realize the second inflation, the field should roll down slowly, then we need $V'' < H^2$. These two conditions are incompatible.

There are several attempts to overcome the problem. Recently Linde constructs the potential which has sharp peak near the false vacuum [4]. In this potential, the tunneling occurs and at the same time slow-rolling is allowed after the tunneling, then the second inflation can be realized. But, it is still unclear what is the physical mechanism for the appearance of the sharp peak in the potential.

A more detailed study of the tunneling process is needed to tackle the problem. In the imaginary-time path-integral formalism, the tunneling is described by the solution of the Euclidean field equation. The solution gives the saddle-point of the path-integral. Then the solution determines the semi-classical exponent of the decay rate $\exp(-S_E(\phi_B))$, where S_E is the Euclidean

action. In the case the curvature around the barrier is small compared with the Hubble, the solution is given by the Hawking Moss (HM) solution, which stays at the top of the barrier through the whole Euclidean time [5]. Recently Rubakov and Sibiryakov give the interpretation of the HM solution in the de Sitter spacetime using the constrained instanton method [6, 7]. They show the HM solution does not represent the false vacuum decay. This is because the HM solution does not satisfy the boundary condition that the field exists in the false vacuum at the infinite past. One should consider a family of the almost saddle-point configurations instead of the true solution of the Euclidean field equation. They show although the decay rate is determined by the HM solution, the structure of the field after tunneling is determined by the other configuration which is one of the almost saddle-point solutions. In the constrained instanton method, one introduces the constraint to define the subspace in the functional space and looks for the almost saddle-point solution. One must choose the constraint so that the almost saddle-point solution is contained in the region which is expected to dominate the path-integral. One way is to consider the valley region of the functional space [8, 9]. Along the valley line, the action varies most gently. Then it is reasonable to take a configuration on the valley line as the almost saddle-point configuration. We will call the configuration on the valley line the valley bounce ϕ_V.

Their analysis opens up a new possibility to overcome the problem. Suppose that one of the valley bounces describes the tunneling and the inside of the bubble created from this valley bounce is our open universe. The initial condition of the tunneling field in the open universe is determined by the valley bounce. If the field appears sufficiently far from the top at the nucleation, the large fluctuations can be avoided. During the tunneling, fluctuations of the tunneling field are generated. These fluctuations are stretched during the second inflation and observed in the open universe.

In this paper, we extend the valley method developed by Aoyama.et.al [9] to the de Sitter spacetime. Taking the assumption that one of the valley bounces describes the tunneling and inside the bubble created from the valley bounce is our universe, the fluctuations generated during the tunneling are calculated by defining the fluctuations which are relevant to the observable in the open universe as those orthogonal to the gradient of the action. Then we show an open universe can be constructed from the valley bounce and the fluctuations can be generated with the appropriate properties. The paper is organized as follows. In the next section we review the formalism to describe the false vacuum decay in the de Sitter spacetime. Then we explain the role of the configurations on the valley of the action, i.e. valley bounces. We derive the valley equation which determines the valley bounce. In section 3, we solve the valley equation analytically using the piece-wise quadratic potential and fixed background approximation. Then the structure of the valley is shown. In section 4, we explain the scenario emphasizing the role of the valley bounce and show that a simple model for an open universe can be constructed without introducing the fine-tuning of the potential. In section 5, we calculate observable fluctuations in the open universe from the valley bounce. The power spectrum of the curvature perturbations is calculated and these fluctuations are shown to be compatible with the observations. In section 6, we summarize the results.

3

2 Valley method in de Sitter spacetime

First we review the formalisms which are necessary to describe the false vacuum decay in the de Sitter space. We want to examine the case in which the gravity comes to play a role. Unfortunately, we have not known how to deal with quantum gravity effect yet. So, we study the case in which we can treat gravity at the semi-classical level. That is, we treat the problem within the framework of the field theory in a fixed curved spacetime [6]. The potential relevant to the tunneling is given by

$$V(\phi) = \epsilon + V_T(\phi). \tag{1}$$

We assume ϵ is of the order M_*^4 and $V_T(\phi)$ is of the order M^4. We study the case M is small compared to M_*, $M \ll M_*$. Then the geometry of the spacetime is fixed to the de Sitter spacetime with $H = M_*^2/M_p$,where $M_p^{-2} = 8\pi G/3$. We consider the situation in which the potential $V_T(\phi)$ has the false vacuum at $\phi = \varphi_F$ and the top of the barrier at $\phi = \varphi_T$. Since the background metric is fixed, we can change the origin of the energy freely. We choose $V_T(\phi_F) = 0$. Following, we work in units with $H = 1$.

The decay rate is given by the imaginary part of the path-integral

$$Z = \int [d\phi] \exp\left(-S_E(\phi)\right), \tag{2}$$

where S_E is the Euclidean action relevant to the tunneling. The dominant contribution of this path-integral is given by the configurations which have $O(4)$ symmetry [10]. So, we assume the background metric and the field to have the form

$$
\begin{aligned}
ds^2 &= d\sigma^2 + a(\sigma)^2 \left(d\rho^2 + \sin^2\rho\, d\Omega\right), \\
\phi &= \phi(\sigma),
\end{aligned}
\tag{3}
$$

where $a(\sigma) = \sin\sigma$. Then, the Euclidean action of $\phi(\sigma)$ is given by

$$S_E = 2\pi^2 \int d\sigma \left(a^3 \left(\frac{1}{2}\phi'^2 + V_T(\phi)\right)\right). \tag{4}$$

The saddle-point of this path-integral is determined by the Euclidean field equation $\delta S_E/\delta\phi{=}0$;

$$\phi'' + 3\cot\sigma\,\phi' - V_T'(\phi) = 0. \tag{5}$$

We impose the regularity conditions at the time when $a(\sigma) = 0$ as

$$\phi'(\sigma = 0) = \phi'(\sigma = \pi) = 0. \tag{6}$$

We represent the solution of this equation as $\phi_B(\sigma)$. If the fluctuations around the solution have a negative mode, it gives the imaginary part to the path-integral and this solution contributes to the decay dominantly. The decay rate Γ is evaluated by

$$\Gamma \sim \exp(-S_E(\phi_B)). \tag{7}$$

4

The equation has two types of the solutions depending on the shape of the potential. If the curvature around the barrier is large compared with the Hubble scale, then the Coleman De Luccia (CD) solution and the Hawking Moss (HM) solution exist [5, 10]. Since the CD solution has lower action than that of the HM solution, the decay is described by the CD solution. The analytic continuation of this solution to Lorentzian spacetime describes the bubble of the true vacuum. On the other hand, in the case the curvature around the barrier is small compared with the Hubble scale, only the HM solution exists. This solution is a trivial solution $\phi = \varphi_T$. The meaning of the HM solution is somewhat ambiguous. There are several attempts to interpret this tunneling mode. One way is to use the stochastic approach [12]. It has been demonstrated that the decay rate given by eq.(7) coincides with the probability of jumping from the false vacuum φ_F onto the top of the barrier φ_T due to the quantum fluctuations.

Recently, Rubakov and Sibiryakov gave the interpretation of the HM solution using the constrained instanton method [6, 7]. The main idea is to consider a family of the almost saddle-point configurations instead of the true solution of the Euclidean field equation, i.e. the HM solution. The motivation comes from the boundary condition. They take the boundary condition that the state of the quantum fluctuations above the classical false vacuum is the conformal vacuum. For this boundary condition they show the field should not be constant at $0 < \sigma < \pi$ and the HM solution is excluded by this boundary condition. Then one should seek the other configurations which obey the boundary condition and dominantly contribute to the path-integral. In the functional integral, the saddle-point solution gives the most dominant contribution, but the contribution from a family of almost saddle-point configurations which have almost the same action with that of the saddle-point solution should also be included. To seek the almost saddle-point solution, one introduces the constraint to the path integral. The constraint selects the subspace of the functional space. The minimum in this subspace satisfies the equation of motion with constraint instead of the field equation. This minimum corresponds to the almost saddle-point configuration which is slightly deformed from the HM solution. Since the HM solution gives the minimum action, the decay rate is determined by the HM solution. But the structure of the field after tunneling can be determined by the one of the almost saddle-point configuration. They found that the configuration describes the bubble of the true vacuum in the Lorentzian spacetime. Then, they conclude that even in the case only the HM solution exists, the result of the tunneling process can be the bubble of the true vacuum which is described by one of the almost saddle-point configurations.

In the constrained instanton method, the validity of the method depends on the choice of the constraint [9, 13]. We should choose the constraint so that the almost saddle-point solution is contained in the region which is expected to dominate the path-integral. Since the action varies most gently along the valley line, we consider the valley region of the action [8, 9].

In the false vacuum decay process in the flat spacetime, the configurations along the valley line have physical meanings [14]. These configurations actually dominate the path-integral in the presence of the low energy incoming particles. If the incoming particles exist, the path-integral which describes the decay is given by $\int [d\phi] \phi^q \exp(-S_E(\phi))$. The effect of the incoming particles deforms the saddle-point. As long as the energy of these incoming particles is low, the deformed configurations belong to the valley. This is because in deforming the configurations from the saddle-point solution, the configurations on the valley line can be obtained most easily compared

with the other configurations with the same action. Thus, the configurations on the valley play a crucial role to calculate the decay rate or the cross section when the initial state is of higher energy than the ground state. In the de Sitter space time, the choice of the quantum states of the quantum fluctuations above a given classical false vacuum will affect the tunneling process considerably [6]. Hence, we think the configurations on the valley line in the de Sitter spacetime may also play an important role, though it is not easy to identify the corresponding quantum state.

Taking into account the above fact, it is desirable to analyze the structure of not only the solution of the Euclidean field equation but also the configurations on the valley line. One way to fined the configurations on this valley line is to use the valley method developed by Aoyama.et.al [9]. To obtain the intuitive understanding of this method, consider the system of the field ϕ_i. Here i stands for the discretized coordinate label and we take the metric as δ_{ij}. In the valley method the equation which identifies the valley line in the functional space is given by

$$D_{ij}\partial_i S = \lambda\,\partial_i S, \quad D_{ij} = \partial_i\partial_j S, \tag{8}$$

where $\partial_i = \partial/\partial\phi_i$. Since the equation (8) has one parameter λ, the equation defines a trajectory in the space of ϕ. The parameter λ is one of the eigen value of the matrix D_{ij}. On the trajectory the gradient vector $\partial_i S$ is orthogonal to all the eigenvectors of D_{ij} except for the eigenvector of the eigen value λ. The equation can be rewritten as

$$\partial_i\left(\frac{1}{2}(\partial_j S)^2 - \lambda S\right) = 0. \tag{9}$$

Then the solution extremizes the norm of the gradient vector $\partial_i S$ under the constraint $S =$const., where λ plays the role of the Lagrange multiplier. Such solution can be found each hypersurface of constant action, then the solutions of the equation form a line in the functional space. If we take λ as the one with the smallest value, then the gradient vector is minimized and the action varies most gently along this line. This is a plausible definition of the valley line. We will call the configuration on the valley line of the action the valley bounce ϕ_V and the trajectory they form the valley trajectory.

We shall formulate the valley method in the de Sitter spacetime. The most convenient way is to use the variational method eq.(9). We shall define the valley action by

$$S_V = S_E - \frac{1}{2\lambda}\int d\sigma\sqrt{g}\left(\frac{1}{\sqrt{g}}\frac{\delta S_E}{\delta\phi}\right)^2. \tag{10}$$

The valley bounce is obtained by varying the action S_V. The equation which determines the valley bounce $\delta S_V/\delta\phi = 0$ is a fourth order differential equation. We introduce the auxiliary field f to cancel the fourth derivative term [14];

$$S_f = \frac{1}{2\lambda}\int d\sigma\sqrt{g}\left(f - \frac{1}{\sqrt{g}}\frac{\delta S_E}{\delta\phi}\right)^2. \tag{11}$$

Then the valley action becomes

$$S_V + S_f = S_E + \frac{1}{2\lambda}\int d\sigma\sqrt{g}f^2 - \frac{1}{\lambda}\int d\sigma f\frac{\delta S_E}{\delta\phi}. \tag{12}$$

6

Taking the variation of this action with respect to f and ϕ, we obtain the equations for ϕ and f;

$$\frac{1}{\sqrt{g}}\frac{\delta S_E}{\delta \phi} = f,$$

$$\int d\sigma' \frac{\delta^2 S_E}{\delta \phi(\sigma)\delta\phi(\sigma')} f(\sigma) = \lambda\sqrt{g}f(\sigma). \tag{13}$$

Using $a(\sigma) = \sin\sigma$, the valley equation which determines the structure of the valley bounce is given by

$$\phi'' + 3\cot\sigma\, \phi' - V_T'(\phi) = -f,$$
$$f'' + 3\cot\sigma\, f' - V_T''(\phi)f = -\lambda f. \tag{14}$$

The fluctuations around the valley bounce can be expanded by the eigenmodes $g_{\alpha,n}(\sigma)$ with the eigenvalue $\rho_{\alpha,n}$ of the operator $(\delta S_E^2/\delta\phi\delta\phi)_{\phi_\alpha}$;

$$g_{\alpha,n}'' + 3\cot\sigma\, g_{\alpha,n}' - V_T''(\phi)g_{\alpha,n} = -\rho_{\alpha,n}g_{\alpha,n}. \tag{15}$$

Since λ is one of the $\rho_{\alpha,n}$ with the smallest value, the gradient of the action $f(\sigma)$ is orthogonal to the other eigenmodes with $\rho_{\alpha,n} \neq \lambda$. To ensure that the valley bounce gives the imaginary part to the path-integral, the fluctuations around the valley bounce should have one negative eigenvalue ρ_-.

In the next section, we solve the valley equation and clarify the structure of the valley bounce. Solving the valley equation is the eigenvalue problem of the two variables, it is desirable to solve the equation analytically to confirm the existence of the solutions. The valley bounce can have a thick-wall profile. In the flat spacetime, there exists the attempt to treat thick-wall solutions analytically by constructing the piece-wise quadratic potentials [11]. In the next section, we extend the attempt to the de Sitter spacetime and solve not only the Euclidean field equation but also the valley equation analytically.

3 Valley bounces

3.1 The construction of Valley bounces

To solve the valley equation developed in the last section, we construct the piece-wise quadratic potential. We connect two parabola. In the potential the true vacuum is absent. But this is not essential in calculations. In fact we have solved numerically the valley equation for several potentials and found this model is sufficient to discuss the generic feature of the valley bounce.

The potential which we study is

$$V_T(\phi) = \begin{cases} \frac{1}{2}m_F^2(\phi - \varphi_F)^2, & -\infty < \phi < 0, \\ -\frac{1}{2}m_T^2(\phi - \varphi_T)^2 + \eta, & 0 \leq \phi < \infty, \end{cases} \tag{16}$$

where η is of the order M^4. We require that the potential and its derivative are connected smoothly at the connection point $\phi = 0$. From this condition, we obtain

$$
\begin{aligned}
\varphi_T &= -\frac{m_F^2}{m_T^2}\varphi_F, \\
\varphi_F &= -\sqrt{\frac{2m_T^2\,\eta}{m_F^2(m_F^2 + m_T^2)}}.
\end{aligned}
\tag{17}
$$

φ_T and φ_F have a mass scale of the order M^2/m_T. Thus, we rescale the field as $\phi \to (M^2/m_T)\phi$ and $f \to (M^2/m_T)f$.

First we solve the Euclidean field equation;

$$
\phi'' + 3\cot\sigma\,\phi' - V_T'(\phi) = 0.
\tag{18}
$$

If one puts $z = -\cos\sigma$ and $Y(z) = \sqrt{1 - z^2}(\phi - \varphi_i)$, the equation reduces to the associated Legendre differential equation

$$
(1 - z^2)\frac{d^2Y}{dz^2} - 2z\frac{dY}{dz} + \left[\nu_i(\nu_i + 1) - \frac{\mu^2}{1 - z^2}\right]Y = 0,
\tag{19}
$$

where $\mu = 1$ and ν_i is given by

$$
\nu_T = \sqrt{\frac{9}{4} + m_T^2} - \frac{1}{2}, \quad \nu_F = \sqrt{\frac{9}{4} - m_F^2} - \frac{1}{2}.
\tag{20}
$$

Here, $i = T$ for $-\infty < \phi < 0$ and $i = F$ for $0 \le \phi < \infty$. The independent solutions of the equation are given by the associated Legendere function of the first and second kinds, $P_{\nu_i}^1(z)$ and $Q_{\nu_i}^1(z)$. $P_\nu^1(z)$ is regular at $z \to 1$. Since these functions behave at $z \to -1$ as

$$
\begin{aligned}
P_\nu^1(z) &\to -2^{1/2}\sin(\pi\nu)\pi^{-1}(1 + z)^{-1/2}, \\
Q_\nu^1(z) &\to -2^{-1/2}\cos(\pi\nu)(1 + z)^{-1/2},
\end{aligned}
\tag{21}
$$

the combination of these solutions

$$
B_\nu^\mu(z) = P_\nu^\mu(z) + \left(-\frac{2}{\pi}\tan(\pi\nu)\right)Q_\nu^\mu(z)
\tag{22}
$$

is regular at $z \to -1$. Then the solution which satisfies the boundary condition is given by

$$
\phi_B = \begin{cases}
\varphi_F + \dfrac{1}{\sqrt{1 - z^2}}\,A_F\,B_{\nu_F}^1(z), & -1 \le z < z_0, \\[2ex]
\varphi_T + \dfrac{1}{\sqrt{1 - z^2}}\,A_T\,P_{\nu_T}^1(z), & z_0 \le z \le 1,
\end{cases}
\tag{23}
$$

where $\phi_B(z_0) = 0$. Since the potential is constructed to be smooth to its first derivative, we demand ϕ_B and its first derivative must be continuous at $z = z_0$. Then the coefficients A_i are determined in terms of z_0;

$$
A_F(z_0) = -\frac{\varphi_F\sqrt{1 - z_0^2}}{B_{\nu_F}^1(z_0)}, \quad A_T(z_0) = -\frac{\varphi_T\sqrt{1 - z_0^2}}{P_{\nu_T}^1(z_0)}.
\tag{24}
$$

The junction time z_0 is determined by $\phi_B(z_0) = 0$;

$$\varphi_F P^1_{\nu_T}(z_0) B^2_{\nu_F}(z_0) - \varphi_T P^2_{\nu_T}(z_0) B^1_{\nu_F}(z_0) = 0. \tag{25}$$

If the algebraic equation for z_0 has a solution, this gives the CD solution. The condition for the existence of the solution restricts the parameter m_i. We see this condition is approximately given by $m_T^2 > 4$.

Next we shall solve the valley equation. Equation for f is given by

$$f'' + 3 \cot \sigma \, f' - V_T''(\phi) f = -\lambda f. \tag{26}$$

The regularity conditions are the same with that of ϕ. Then, the general solution which satisfies the boundary conditions is given by

$$f = \begin{cases} \dfrac{1}{\sqrt{1-z^2}} G_F \, B^1_{\nu_{F\lambda}}(z), & -1 \leq z < z_\lambda, \\[3mm] \dfrac{1}{\sqrt{1-z^2}} G_T \, P^1_{\nu_{T\lambda}}(z), & z_\lambda \leq z \leq 1, \end{cases} \tag{27}$$

where

$$\nu_{T\lambda} = \sqrt{\frac{9}{4} + (m_T^2 + \lambda)} - \frac{1}{2}, \quad \nu_{F\lambda} = \sqrt{\frac{9}{4} - (m_F^2 - \lambda)} - \frac{1}{2}. \tag{28}$$

From the junction conditions, we obtain

$$G_F = \frac{P^1_{\nu_{T\lambda}}(z_\lambda)}{B^1_{\nu_{F\lambda}}(z_\lambda)} G_T, \quad G_F = \frac{P^2_{\nu_{T\lambda}}(z_\lambda)}{B^2_{\nu_{F\lambda}}(z_\lambda)} G_T. \tag{29}$$

The equation has solutions only if z_λ satisfies the following equation

$$P^1_{\nu_{T\lambda}}(z_\lambda) B^2_{\nu_{F\lambda}}(z_\lambda) - P^2_{\nu_{T\lambda}}(z_\lambda) B^1_{\nu_{F\lambda}}(z_\lambda) = 0, \tag{30}$$

which determines the junction time z_λ. Next we solve the equation for ϕ;

$$\phi'' + 3 \cot \sigma \, \phi' - V_T'(\phi) = -f. \tag{31}$$

In the equation, f acts as the source. We can see that the special solution is given by

$$\phi - \varphi_i = \frac{f}{\lambda}. \tag{32}$$

Then the solution which satisfies the boundary condition is given by

$$\phi_V = \begin{cases} \varphi_F + \dfrac{1}{\sqrt{1-z^2}} A_F \, B^1_{\nu_F}(z) + \dfrac{1}{\lambda\sqrt{1-z^2}} G_F \, B^1_{\nu_{F\lambda}}(z), & -1 \leq z < z_\lambda, \\[3mm] \varphi_T + \dfrac{1}{\sqrt{1-z^2}} A_T \, P^1_{\nu_T}(z) + \dfrac{1}{\lambda\sqrt{1-z^2}} G_T \, P^1_{\nu_{T\lambda}}(z), & z_\lambda \leq z \leq 1. \end{cases} \tag{33}$$

9

From the junction conditions, we obtain the coefficients

$$
\begin{aligned}
A_F &= \sqrt{1-z_\lambda^2} \, \frac{P_{\nu_T}^2(z_\lambda)(\varphi_F - \varphi_T)}{P_{\nu_T}^1(z_\lambda)B_{\nu_F}^2(z_\lambda) - P_{\nu_T}^2(z_\lambda)B_{\nu_F}^1(z_\lambda)}, \\
G_F &= -\lambda \sqrt{1-z_\lambda^2} \, \frac{\varphi_F P_{\nu_T}^1(z_\lambda)B_{\nu_F}^2(z_\lambda) - \varphi_T P_{\nu_T}^2(z_\lambda)B_{\nu_F}^1(z_\lambda)}{B_{\nu_{F\lambda}}^1(z_\lambda)(P_{\nu_T}^1(z_\lambda)B_{\nu_F}^2(z_\lambda) - P_{\nu_T}^2(z_\lambda)B_{\nu_F}^1(z_\lambda))}, \\
A_T &= \frac{B_{\nu_F}^2(z_\lambda)}{P_{\nu_T}^2(z_\lambda)} A_F, \qquad G_T = \frac{B_{\nu_{F\lambda}}^2(z_\lambda)}{P_{\nu_{T\lambda}}^2(z_\lambda)} G_F.
\end{aligned}
\tag{34}
$$

Note that in this model the deformation of the configurations is essentially determined by z_λ. If $z_\lambda = z_0$, G_i becomes 0, so $\phi_V = \phi_B$ as expected.

To ensure that the valley bounce plays a role instead of the true saddle point solution, we must examine the fluctuations around the valley bounce have one negative mode and give the imaginary part to the path-integral. The equation which determines the eigenmodes is given by

$$
g_n'' + 3 \cot\sigma \, g_n' - V_T''(\phi)g_n = -\rho_n g_n.
\tag{35}
$$

Then, the eigenvalue equation which determines the eigenvalue ρ_n of these eigenmodes becomes

$$
P_{\nu_{T\rho_n}}^1(z_\lambda)B_{\nu_{F\rho_n}}^2(z_\lambda) - P_{\nu_{T\rho_n}}^2(z_\lambda)B_{\nu_{F\rho_n}}^1(z_\lambda) = 0.
\tag{36}
$$

Note that, λ is one of the solutions ρ_n.

We should treat separately the case in which the valley bounce exists around the top of the barrier and passes through only one parabola. We put the solution for f as

$$
f = \sum_{n=0}^{\infty} b_n \cos n\sigma,
\tag{37}
$$

then the equation for f is rewritten as [15]

$$
\sum_{n=0}^{\infty} \Big([(n-1)(n+2) - m_T^2 - \lambda]b_{n-1} - [(n+1)(n-2) - m_T^2 - \lambda]b_{n+1} \Big) \sin n\sigma = 0.
\tag{38}
$$

Thus, b_n converges only when

$$
\lambda = -m_T^2 + n(n+3).
\tag{39}
$$

We put the solution for ϕ as

$$
\phi - \varphi_T = \sum_{n=0}^{\infty} a_n \cos n\sigma,
\tag{40}
$$

then the solution for ϕ is given by

$$
a_n = \frac{1}{\lambda} c_n.
\tag{41}
$$

The eigenvalue of the eigenmode at the valley bounce is given by

$$
\rho_n = -m_T^2 + n(n+3).
\tag{42}
$$

10

3.2　The structure of the valley

Using the analytic solution of ϕ and f, we show the structure of the valley. Remember that we have rescaled the field as $\phi \to (M^2/m_T)\phi$ and $f \to (M^2/m_T)f$. Following, for completeness, we consider the two types of the potential; $(1)m_T^2 > 4$ and $(2)m_T^2 < 4$.

$(1)m_T^2 > 4$

There exist two solutions in the Euclidean field equation; the CD solution and the HM solution. For example, we take $m_T^2 = 7$, $m_F^2 = 2.2$ and $\eta = 0.6M^4$ (Fig.1). The behaviors of the CD solution $\phi(\sigma)$, the eigenmode with the negative eigenvalue $g_-(\sigma)$ and the scale factor $a(\sigma)$ are shown in Fig.2. The CD solution has one negative eigenvalue $\rho_{CD,-} = -4.7$ and the smallest positive eigenvalue is $\rho_{CD,+} = 3$. Since the CD solution gives the saddle-point of the path-integral, we analyze the valley trajectory which contains the CD solution. At the CD solution on the valley trajectory, $f = 0$. The valley bounce near the CD solution is obtained by deforming the CD solution; $\phi_V = \phi_{CD} + \triangle\phi_V$. The deformation $\triangle\phi_V$ is due to the source term $f \neq 0$ in the equation for ϕ. The equation for f is almost the same with that for the eigenmode g at the CD solution. Thus, λ is given by $\lambda = \rho_{CD} + \triangle\lambda$. To ensure the action varies most gently along the valley trajectory, ρ_{CD} should be the eigenvalue of the smallest value. In this case, ρ_{CD} has one negative eigenvalue, so we take λ at the CD solution as $\lambda(\phi_{CD}) = \rho_{CD,-}$ or $\lambda(\phi_{CD}) = \rho_{CD,+}$.

First examine the valley trajectory associated with the negative eigenvalue $(\lambda(\phi_{CD}) = \rho_{CD,-})$. The valley bounce obtained from the analytic results developed in the previous section is shown in the lower-panel of Fig.3. Since $\rho_{CD,-}$ is the lowest eigenvalue, f does not have a node. In the equation for ϕ, f acts as the force. So, the valley bounce in this trajectory is obtained by deforming the CD solution adding a one-direction force f. If $f > 0$, the valley bounce has a structure of the small bubble and if $f < 0$ it has a structure of the large bubble [14]. We plot the action along this trajectory in lower-panel of Fig.4. The CD solution gives the maximum of the action.

Next consider the valley trajectory associated with the smallest positive eigenvalue $(\lambda(\phi_{CD}) = \rho_{CD,+})$. We show the valley bounce in this trajectory in the upper panel of Fig.3. Since $\rho_{CD,+}$ is the next to the lowest eigenvalue, f has one node. In the equation for ϕ, f acts as the mass term of ϕ. So, in this trajectory, the valley bounce is obtained by modifying the mass of the field ϕ. It is known that the CD solution is smoothly connected to the HM solution if one decreases the mass around the top of the barrier [16]. Then, it is expected that this trajectory connects the CD solution and the HM solution. The action along this valley trajectory is shown in the upper-panel of Fig.4. Since the degeneracy occurs in λ, we take the horizontal coordinate as the 'norm' of the solution $|\Phi| = \sqrt{2\pi^2 \int a^3(\phi - \varphi_T)^2}$ [14]. We see the CD solution is the minimum and the HM solution is the maximum of the action and these solutions are smoothly connected on this trajectory as expected.

$(2)m_T^2 < 4$.

The saddle point solution is the HM solution. For example we take $m_T^2 = 2$, $m_F^2 = 0.5$ and $\eta = 0.1M^4$ (Fig.5). The HM solution has one negative eigenvalue $\rho_{HM,-} = -2$ and the

smallest positive eigenvalue is given by $\rho_{HM,+} = 2$. The generic feature of the valley bounce is understood by the simple analysis of the case in which the valley bounce exists only in one parabola. First consider the valley trajectory associated with the negative eigenvalue. The solution of the valley equation is essentially has a form $f = \lambda(\phi - \varphi_T) = \text{const}$. This solution does not represent the tunneling, so we seek the trajectory associated with the smallest positive eigenvalue $\lambda(\phi_{HM}) = \rho_{HM,+}$. The solution of the valley equation is given by $\phi - \phi_T \propto \cos\sigma$ and $f = \lambda(\phi - \phi_T)$ (Fig.6). In this trajectory, the HM solution gives the minimum of the action (Fig.7). The action grows as the variation of the field becomes large, but the increase is relatively gentle.

The fluctuations around the valley bounce should have one negative mode to ensure that the valley bounce plays a role instead of the HM solution. The valley bounce has a lowest eigenvalue $\rho_{V,-} < \lambda(\phi_V)$, which is negative on this trajectory. Since this is the unique negative eigenvalue, the gaussian integration of the fluctuations around this valley bounce gives the imaginary part to the path-integral. Then, the valley bounce contributes to the false vacuum decay and describes the creation of the bubble of the true vacuum.

4 An open universe from valley bounce

Using the results developed so far, we will study a model for an open universe inside the bubble. Since the radius of the bubble R is small compared with the Hubble horizon [10], then the curvature scale is greater than the energy of the matter inside the bubble ρ_M even if the whole energy of the false vacuum is converted to the energy of the matter, $\rho_M/M_p^2 \sim H^2 < 1/R^2$ [2]. Thus, we need the second inflation in the bubble. To realize the second inflation inside the bubble, the field should roll slowly down the potential. It requires that the curvature of the potential is small compared with the Hubble. To avoid the *ad hoc* fine-tuning of the potential, we will assume the requirement is satisfied for all region of the potential. Since $m_T < H$, the solution of the Euclidean field equation is given by the HM solution. If the tunneling is described by the HM solution, the field appears at the top of the barrier. Then large fluctuations are generated because at the top of the barrier the field experiences the quantum diffusion rather than the classical potential force. Fluctuations in this diffusion dominated epoch make the inhomogeneous delay of the start of the classical motion, thus make large fluctuations.

The above argument is based on the assumption that the HM solution describes the false vacuum decay. However, it seems to be possible that one of the valley bounces describes the decay instead of the HM solution. One of the grounds is that in the de Sitter spacetime, the choice of the quantum states of the quantum fluctuations above the false vacuum will affect the tunneling process considerably [6]. In the de Sitter spacetime, one has to specify the state of the quantum fluctuations of the field besides specifying the classical vacuum which is the average value of the field i.e. φ_F. The dominant configuration in the path-integral depends on the initial state of the quantum fluctuations above the false vacuum. In case of the flat spacetime, if the initial state is of higher energy than the ground state, the dominant configuration is given by one of the valley bounces instead of the bounce solution [14]. Thus it seems natural to consider the situation in which one of the valley bounces describes the tunneling and inside the created bubble

is our universe, although it is difficult to identify the quantum state corresponding to the valley bounce. Hence we take the presumption that one of the valley bounces describes the tunneling and inside the bubble created from the valley bounce is our universe.

A problem about the assumption that an individual valley bounce describes the tunneling is the interpretation of the valley bounce in the Lorentzian spacetime. Our interpretation is that the valley bounce determines the initial condition of the tunneling field in the open universe. Within the fixed background approximation, we can make analytic continuation about the background geometry from the Euclidean de Sitter space (3) (see Fig.8). By the analytic continuation

$$\tau = i(\rho - \pi/2), \ \ \sigma = \sigma, \tag{43}$$

we obtain the Lorenzian de Sitter spacetime (Region II)

$$ds^2 = d\sigma^2 + a(\sigma)^2 \left(-d\tau^2 + \cosh^2 \tau d\Omega^2\right). \tag{44}$$

We take the nucleation surface at $\tau = 0$. Region II is almost covered by the false vacuum. Then we assume the effect which modifies the dominant configuration from the HM solution to the valley bounce also modifies the classical motion of the field in this region. The field obeys the equation analytically continued from the valley equation (14). The solution of the equation is given by the analytic continuation of the valley bounce. On the other hand, because the bubble expands classically at a velocity rapidly approaching the velocity of light, inside the expanding bubble is well described by the usual classical equation of motion. On the light-cone of the center of the bubble $\sigma = \pi$, the coordinate is singular $a(\sigma) = 0$. We continue to the interior of the light-cone (Region I) by

$$r = \tau + i\frac{\pi}{2}, \ \ t = i(\sigma - \pi). \tag{45}$$

The resulting metric is given by

$$ds^2 = -dt^2 + b(t)^2 \left(dr^2 + \sinh^2 r d\Omega^2\right), \tag{46}$$

The expanding bubble is homogeneous and isotropic on the hypersurface on the hyperbolic time slicing $t = const$. The interior of the light-cone can be viewed as an open Friedman-Robertson-Walker universe with scale factor $b(t)$. The initial condition of the tunneling field on $t = 0$ hypersurface is determined by the behavior of valley bounce at $\sigma = \pi$. After that time, the evolution of the field is described by the classical field equation.

Under these assumptions, we will construct a model for an open inflation in the simple model with the polynomial form of the potential. We connect the linear potential at the point the field appears after the tunneling $\phi = \phi_*$,

$$V(\phi) = V_* - \mu^3(\phi - \phi_*), \qquad (\phi > \phi_*). \tag{47}$$

We demand the potential and its derivative are connected smoothly at the connection point ϕ_*. Then we obtain

$$
\begin{aligned}
V_* &= \epsilon + \eta - \frac{1}{2}m_T^2(\phi_* - \varphi_T)^2, \\
\mu^3 &= m_T^2(\phi_* - \varphi_T).
\end{aligned}
\tag{48}
$$

The initial conditions of the field in the open universe are given by the valley bounce

$$\phi(t=0) = \phi_0(z=1) = \phi_*, \quad \dot{\phi}(t=0) = 0. \tag{49}$$

The field evolves obeying the classical field equation;

$$\ddot{\phi} + 3\coth t \, \dot{\phi} + V'(\phi) = 0, \tag{50}$$

then the solution of ϕ satisfies

$$\dot{\phi}(t) = \mu^3 \frac{\cosh^3 t - 3\cosh t + 2}{3\sinh^3 t}. \tag{51}$$

In the small t this behaves as $(1/4)\mu^3 t$. The classical motion during one expansion time is given by $|\dot{\phi}|H^{-1}$. On the other hand the amplitude of the quantum fluctuations is given by $\delta\phi \sim H$. The curvature perturbation $\mathcal{R}$ produced by the quantum fluctuations is approximately given by the ratio of these two quantities;

$$\mathcal{R} \sim \frac{\delta\phi}{|\dot{\phi}|H^{-1}} \sim \frac{H^3}{\mu^3} \sim \frac{H^2}{m_T^2}\left(\frac{H}{\phi_* - \varphi_T}\right). \tag{52}$$

This should be of the order 10^{-5} from the observation of the cosmic microwave background (CMB) anisotropies. If $|\phi_* - \varphi_T| < H$, as in the case the HM solution describes the tunneling, $\mathcal{R} > 1$ and the scenario cannot work well. Fortunately, from Fig.7, we see for appropriate λ, the valley bounce gives the initial condition as $|\phi_* - \varphi_T| \sim O(1)(M^2/m_T)$, which is larger than the Hubble if $M > H$. For this initial condition, the potential force works and the field rolls slowly down the potential according to eq.(50). We expect the curvature perturbation can be suppressed for the valley bounce

5 Fluctuations in the open universe

In this section, we will calculate the observable fluctuations in the open universe from the valley bounce based on a model described in the previous section. We will assume the decay is described by one of the valley bounces ϕ_0. Then we take one specific λ in the following calculations. Under this assumption, we calculate the observable fluctuations in the open universe.

5.1 Fluctuations around the valley bounce

We first calculate the fluctuations around the valley bounce in the Euclidean spacetime. The Euclidean action can be expanded around the valley bounce ϕ_0 as

$$S_E(\phi) = S_E(\phi_0) + \int d^4x \sqrt{g} \frac{1}{\sqrt{g}} \left.\frac{\delta S_E}{\delta\phi}\right|_{\phi_0} \delta\phi(\sigma) + \frac{1}{2}\int\int d^4x d^4x' \left.\frac{\delta^2 S_E}{\delta\phi(x)\delta\phi(x')}\right|_{\phi_0} \delta\phi(x)\delta\phi(x'). \tag{53}$$

Since the valley bounce does not obey the field equation, then the first order derivative term does not vanish. This can be avoided by constraining the space of the fluctuations to that orthogonal to the gradient of the action;

$$\int d^4x \sqrt{g} \left(\frac{1}{\sqrt{g}} \frac{\delta S_E}{\delta \phi} \bigg|_{\phi_0} \delta\phi \right) = 0. \tag{54}$$

We must calculate the physical observable like two-point correlation function in the bubble described by ϕ_0. For example, consider the variance of the scalar field $\langle \phi^2 \rangle - \langle \phi \rangle^2$, where $\langle \ \rangle$ is average over ρ and Ω. Analytically continuing to the Lorentzian spacetime, this corresponds to the average over the space in open universe. Since the variables which depend only on σ obey the relation

$$\langle \phi_0 \rangle = \phi_0, \quad \langle \delta\phi(\sigma) \rangle = \delta\phi(\sigma), \tag{55}$$

we can show

$$\langle \phi^2 \rangle - \langle \phi \rangle^2 = \langle \delta\phi(\sigma, \rho, \Omega)^2 \rangle - \langle \delta\phi(\sigma, \rho, \Omega) \rangle^2. \tag{56}$$

So the observable in the open universe can be evaluated from inhomogeneous fluctuations which do not have $O(4)$ symmetric configurations. In the de Sitter spacetime, inhomogeneous fluctuations are expanded by scalar harmonics

$$\delta\phi(\sigma, \rho, \Omega) = \int dp \, S_p(\sigma) Y_{plm}(\rho, \Omega). \tag{57}$$

The harmonics obeys the orthogonal relation between different p^2. Now the gradient vector is given by $f(\sigma)$ which is the mode of $p^2 = -1$. Then, the inhomogeneous fluctuations which depend on ρ and Ω ($p^2 \neq -1$) are orthogonal to the gradient of the action $f(\sigma)$ automatically.

Fluctuations around the valley bounce ϕ_0 obey the field equation

$$\int dx'^4 \frac{\delta^2 S_E}{\delta\phi(x)\delta\phi(x')} \bigg|_{\phi_0} \delta\phi(x') = 0. \tag{58}$$

In Region II of the Lorenzian de Sitter spacetime;

$$ds^2 = d\sigma^2 + a(\sigma)^2 \left(-d\tau^2 + \cosh^2 \tau d\Omega^2 \right), \tag{59}$$

we assume background field obeys the equation of motion analytically coninued from the valley equation. Then the fluctuations in Region II is obtained by the analytical continuation (45);

$$\tau = i(\rho - \pi/2), \quad \sigma = \sigma. \tag{60}$$

Thus we will solve the equation (58) analytically continuing to Region II. The procedure to solve the equation is the same with that was done in the previous works [17, 18, 19, 20]. We will follow their calculations. Expanding the fluctuations as

$$\delta\phi(\sigma, \tau, \Omega) = \int dp \, S_p(\sigma) Y_{plm}(\tau, \Omega), \tag{61}$$

15

we obtain the equation of the fluctuations

$$\left(\frac{\partial^2}{\partial \tau^2} + 2\tanh\tau \frac{\partial}{\partial \tau} + \frac{l(l+1)}{\cosh^2 \tau}\right) Y_{plm}(\tau, \Omega) = -(1+p^2) Y_{plm}(\tau, \Omega), \tag{62}$$

$$S_p''(\sigma) + 3\cot\sigma S_p'(\sigma) + \left(\frac{1+p^2}{\sin^2 \sigma} - V_T''(\phi_0)\right) S_p(\sigma) = 0, \tag{63}$$

where

$$V_T''(\phi_0) = \begin{cases} m_F^2, & 0 \leq \sigma < \sigma_\lambda, \\ -m_T^2, & \sigma_\lambda \leq \sigma \leq \pi, \end{cases}$$

and $z_\lambda = -\cos\sigma_\lambda$. Here λ is determined by ϕ_0. Since the temporal coordinate τ is included in the harmonics Y_{plm}, the choice of the solution Y_{plm} specifies the vacuum. This choice is related to the initial quantum state of the fluctuations. We will take this initial state as Bunch-Davis vacuum. The equation for $S_p(\sigma)$ can be rewritten as

$$\left(-\frac{d^2}{du^2} + U(u)\right)\left(\frac{S_p(u)}{a(u)}\right) = p^2 \left(\frac{S_p(u)}{a(u)}\right), \tag{64}$$

where

$$a(u) = (\cosh u)^{-1}, \quad U(u) = \frac{V''(\phi_0) - 2}{\cosh^2 u}, \quad \tanh u = -\cos\sigma = z. \tag{65}$$

Since $U(u) \to 0$ as $u \to \pm\infty$, the modes are continuous for $p^2 > 0$. For $u_\lambda < u$, the potential has a valley, then some discrete modes exist for $p^2 < 0$.

First consider the continuous modes. Positive frequency mode should satisfy the Klein-Gordon normalization

$$-i \int dz \ \left[\cosh^2 \tau \, d\Omega \left(\delta\phi_{plm}^+ \ (\partial_\tau \delta\phi_{p'l'm'}^{+*}) - \ (\partial_\tau \delta\phi_{plm}^+) \ \delta\phi_{p'l'm'}^{+*}\right)\right]_{\tau=0} = \delta(p-p')\delta_{ll'}\delta_{mm'}. \tag{66}$$

For simplicity we consider s-wave. The normalized positive frequency mode function of the Bunch-Davis vacuum is given by

$$\delta\phi_{\pm p}^+(\sigma, \tau) = S_{\pm p}(\sigma) Q_p(\tau), \quad Q_p(\tau) = \frac{e^{\pi p/2} e^{-ip\tau} - e^{-\pi p/2} e^{ip\tau}}{\sqrt{2\sinh\pi p} \ \cosh\tau}, \tag{67}$$

where S_p is normalized as

$$\int_{-1}^{1} dz \ S_p(z) S_{p'}^*(z) = \frac{1}{8\pi|p|}\delta(p-p'). \tag{68}$$

Using this mode function, the fluctuations can be expanded as

$$\delta\phi = \int_0^\infty dp \ \left[(\delta\phi_p^+ \ \hat{\boldsymbol{a}}_p + \delta\phi_{-p}^+ \ \hat{\boldsymbol{a}}_{-p}) + (h.c)\right], \tag{69}$$

where $\hat{\boldsymbol{a}}_p$ annihilates the Bunch-Davis vacuum. We take the initial fluctuations $S_p(z)$ at $z = -1$ as the Klein-Goldon normalized mode $F_p^F(z)$ on $-1 \leq z \leq 1$, then we evolve this mode using the field equation to $z = 1$. The resulting mode function is

$$\tilde{S}_p(z) = \begin{cases} F_p^F(z), & -1 \leq z < z_\lambda, \\ \alpha_p F_p^T(z) + \beta_p F_{-p}^T(z), & z_\lambda \leq z \leq 1, \end{cases} \tag{70}$$

16

where

$$F_p^i(z) = \frac{1}{\sqrt{1-z^2}} \frac{1}{4\pi\sqrt{|p|}} \left(a_+^i \Gamma(1-ip) P_{\nu_i}^{ip}(z) - a_-^i \Gamma(1+ip) P_{\nu_i}^{-ip}(z) \right), \tag{71}$$

and

$$a_+^i = \sqrt{\frac{1 + \sqrt{1 - |C_2^i|^2/C_1^{i2}}}{2}}, \quad a_-^i = \left(\frac{C_2^i}{|C_2^i|}\right) \sqrt{\frac{1 - \sqrt{1 - |C_2^i|^2/C_1^{i2}}}{2}},$$

$$C_1^i(p) = 2\pi\left(1 + \frac{\sin^2 \pi\nu_i}{\sinh^2 \pi p}\right), \quad C_2^i(p) = -2\pi^2 \frac{\Gamma[1-ip]}{\Gamma[1+ip]} \frac{\sin \pi\nu_i}{\sinh^2 \pi p} \frac{1}{\Gamma[-ip-\nu_i]\Gamma[1-ip+\nu_i]}.$$

Here, α_p and β_p are determined by the junction conditions at z_λ

$$\alpha_p(z_\lambda) = \left.\frac{F_p^F d_z F_{-p}^T - F_{-p}^T d_z F_p^F}{F_p^T d_z F_{-p}^T - F_{-p}^T d_z F_p^T}\right|_{z_\lambda},$$

$$\beta_p(z_\lambda) = \left.\frac{-F_p^F d_z F_p^T + F_p^T d_z F_p^F}{F_p^T d_z F_{-p}^T - F_{-p}^T d_z F_p^T}\right|_{z_\lambda}, \tag{72}$$

where $d_z = d/dz$. $\tilde{S}_p(z)$ is not normalized on $-1 \le z \le 1$. The normalized mode function is given by

$$S_p(z) = \begin{cases} b_+ F_p^F(z) - b_- F_{-p}^F(z), & -1 \le z < z_\lambda, \\ \\ (b_+ \alpha_p - b_- \beta_{-p}) F_p^T(z) + (b_+ \beta_p - b_- \alpha_{-p}) F_{-p}^T(z), & z_\lambda \le z \le 1, \end{cases} \tag{73}$$

where

$$b_+ = \sqrt{\frac{D_1}{D_1^2 - |D_2|^2}} \sqrt{\frac{1 + \sqrt{1 - |D_2|^2/D_1}}{2}}, \quad b_- = \left(\frac{D_2}{|D_2|}\right) \sqrt{\frac{D_1}{D_1^2 - |D_2|^2}} \sqrt{\frac{1 - \sqrt{1 - |D_2|^2/D_1}}{2}}, \tag{74}$$

and

$$D_1(p) = \frac{1}{2}(|\tilde{\alpha}_p|^2 + |\tilde{\beta}_p|^2 + 1), \quad D_2(p) = \tilde{\alpha}_p \tilde{\beta}_p + \frac{C_2^F}{2C_1^F},$$

$$\tilde{\alpha}_p = \alpha_p a_+^T - \beta_p a_-^{T*}, \quad \tilde{\beta}_p = \beta_p a_+^T - \alpha_p a_-^T. \tag{75}$$

Next consider the discrete modes. We put $p^2 = -\Lambda^2$. The Bunch-Davis positive frequency mode is given by

$$\delta\phi_{\Lambda lm}^+ = S_\Lambda(\sigma) Y_{\Lambda lm}(\tau, \Omega), \tag{76}$$

where

$$Y_{\Lambda lm}(\tau, \Omega) = \sqrt{\frac{\Gamma[\Lambda+l+1]\Gamma[-\Lambda+l+1]}{2}} \frac{P_{\Lambda-1/2}^{-l-1/2}(i\sinh\tau)}{\sqrt{i\cosh\tau}}, \tag{77}$$

and S_Λ is normalized as

$$\int_{-1}^{1} dz |S_\Lambda(z)|^2 = 1. \tag{78}$$

17

From the regularity condition similar to the valley bounce, the solution is given by

$$
\tilde{S}_\Lambda(z) = \begin{cases} \dfrac{\alpha_\Lambda}{\sqrt{1-z^2}} \left(P_{\nu_F}^\Lambda(z) + \beta_\Lambda P_{\nu_F}^{-\Lambda}(z) \right), & -1 \le z < z_\lambda, \\[4mm] \dfrac{1}{\sqrt{1-z^2}} P_{\nu_T}^{-\Lambda}(z), & z_\lambda \le z \le 1, \end{cases}
\tag{79}
$$

where

$$
\beta_\Lambda = \frac{\sin \pi\nu_F}{\pi} \Gamma[1 + \Lambda + \nu_F] \Gamma[\Lambda - \nu_F].
\tag{80}
$$

From the junction condition, α_Λ is given by

$$
\alpha_\Lambda = \left. \frac{P_{\nu_T}^{-\Lambda}}{P_{\nu_F}^\Lambda + \beta_\Lambda P_{\nu_F}^{-\Lambda}} \right|_{z_\lambda}, \qquad \alpha_\Lambda = \left. \frac{d_z P_{\nu_T}^{-\Lambda}}{d_z P_{\nu_F}^\Lambda + \beta_\Lambda d_z P_{\nu_F}^{-\Lambda}} \right|_{z_\lambda}.
\tag{81}
$$

Then Λ is determined by the equation

$$
P_{\nu_T}^{-\Lambda}(d_z P_{\nu_F}^\Lambda + \beta_\Lambda d_z P_{\nu_F}^{-\Lambda}) = d_z P_{\nu_T}^{-\Lambda}(P_{\nu_F}^\Lambda + \beta_\Lambda P_{\nu_F}^{-\Lambda}).
\tag{82}
$$

The mode $\tilde{S}_\Lambda$ is not normalized. The normalized mode is given by

$$
S_\Lambda(z) = N_\Lambda \tilde{S}_\Lambda(z), \quad N_\Lambda = \left(\int_{-1}^1 dz |\tilde{S}_\Lambda(z)|^2 \right)^{-1/2}.
\tag{83}
$$

5.2 Initial fluctuations in the open universe

Fluctuations propagate into the interior of the light-cone $\sigma = \pi(z = 1)$. Since the coordinate system (59) is singular on the light-cone, we make analytic continuation by

$$
r = \tau + i\frac{\pi}{2}, \quad t = i(\sigma - \pi).
\tag{84}
$$

The resulting metric is given by

$$
ds^2 = -dt^2 + b(t)^2 \left(dr^2 + \sinh^2 r \, d\Omega^2 \right),
\tag{85}
$$

where $b(t) = \sinh t$. Since the fluctuations exponentially expand during the second inflation in the bubble, the shortwavelength modes are relevant. The matching condition across the lightcone in the Minkowski limit is given by

$$
\begin{aligned}
F_p^T(\sigma)Q_p(\tau) &\to \frac{-i}{2\sqrt{2p}} \frac{1}{\sqrt{2\sinh \pi p}} R_p(r)(a_+^T e^{\pi p/2} T_p(\eta) - a_-^T e^{-\pi p/2} T_{-p}(\eta)), \\
F_{-p}^T(\sigma)Q_p(\tau) &\to \frac{-i}{2\sqrt{2p}} \frac{1}{\sqrt{2\sinh \pi p}} R_p(r)(a_+^T e^{-\pi p/2} T_{-p}(\eta) - a_-^{T*} e^{\pi p/2} T_p(\eta)),
\end{aligned}
\tag{86}
$$

where

$$
\begin{aligned}
T_p(\eta) &= e^{-ip\eta - \eta}, \; e^\eta = \tanh(t/2), \\
R_p(r) &= \frac{1}{\sqrt{2\pi}} \frac{\sin p\, r}{\sinh r}.
\end{aligned}
\tag{87}
$$

Note that $R_p(r)$ is the normalized scalar harmonics $R_p(r) = Y_{p00}(r)$, where

$$Y_{plm}(r, \Omega) = \frac{p\Gamma[ip+l+1]}{\Gamma[ip+1]} \frac{P_{ip-1/2}^{-l-1/2}(\cosh r)}{\sqrt{\sinh r}} Y_{lm}(\Omega), \tag{88}$$

and Y_{lm} is the usual spherical harmonics. Then, the extension to the general modes with $l \neq 0, m \neq 0$ is straightforwardly given by replacing $R_p(r)$ to $Y_{plm}(r, \Omega)$. We obtain the fluctuations inside the bubble

$$
\begin{aligned}
\delta\phi &= -i \sum_{lm} \int_0^\infty dp \frac{1}{2\sqrt{2p}} Y_{plm}(r, \Omega) \frac{1}{\sqrt{2\sinh \pi p}} \\
&\times \left[\left((e^{\pi p/2} g_1(p, \lambda) T_p(\eta) + e^{-\pi p/2} g_2(p, \lambda) T_{-p}(\eta)) \hat{a}_p \right. \right. \\
&+ \left. \left. (e^{-\pi p/2} g_1^*(p, \lambda) T_{-p}(\eta) + e^{\pi p/2} g_2^*(p, \lambda) T_p(\eta)) \hat{a}_{-p} \right) + (h.c.) \right],
\end{aligned} \tag{89}
$$

where

$$
\begin{aligned}
g_1(p, \lambda) &= a_+^T (b_+ \alpha_p(z_\lambda) - b_- \beta_{-p}(z_\lambda)) - a_-^{T*}(b_+ \beta_p(z_\lambda) - b_- \alpha_{-p}(z_\lambda)), \\
g_2(p, \lambda) &= a_+^T (b_+ \beta_p(z_\lambda) - b_- \alpha_{-p}(z_\lambda)) - a_-^T (b_+ \alpha_p(z_\lambda) - b_- \beta_{-p}(z_\lambda)).
\end{aligned} \tag{90}
$$

This is the initial condition of the fluctuations in the open universe. The discrete mode can be treated in the same way. We obtain the positive frequency mode

$$\delta\phi_\Lambda^+ = N_\Lambda \frac{P_{\nu_T}^{-\Lambda}(\cosh t)}{\sinh t} Y_{\Lambda lm}(r, \Omega). \tag{91}$$

In the limit $t \to 0$, this becomes

$$\delta\phi_\Lambda^+ = \frac{N_\Lambda}{2\Gamma[1+\Lambda]} T_\Lambda(\eta) Y_{\Lambda lm}(r, \Omega), \tag{92}$$

where $T_\Lambda = e^{\Lambda\eta - \eta}$. Using this mode function, the fluctuations can be expanded as

$$\delta\phi = \sum_i \sum_{lm} \delta\phi_{\Lambda_i}^+ \hat{a}_{\Lambda_i} + (h.c). \tag{93}$$

In Fig.9 we plot the solutions Λ for $m_T^2 < 4$ (Case (2) in section 3.1). We also show the normalization factor N_Λ. We find two solutions of Λ. We call the mode with $0 < \Lambda_{sub} < 1$ the subcritical mode and the one with $1 < \Lambda_{sup}$ the supercritical mode [21]. In the case the background solution is given by the HM solution, one supercritical mode with $\Lambda_{sup} = \nu_T = \sqrt{9/4 + m_T^2} - 1/2 > 1$ exists. In the present case, the mass changes m_0^2 to $-m_T^2$ at z_λ, another subcritical mode appears. Note that in the case the CD solution describes the tunneling, the supercritical mode corresponds to the wall fluctuation mode $\delta\phi_w \propto \dot{\phi}_{CD}$ with $\Lambda_{sup} = 2$. Although in the present case the correspondence cannot be held, the behavior of the supercritical mode resembles the wall fluctuation mode.

5.3 Curvature perturbations in the open universe

In this subsection we restore the Hubble scale H. The field evolves with the classical field equation inside the bubble (Region I). We should match the fluctuations (89), (93) to the solution of the field equation with the background field satisfying the classical equation of the motion (50). Fluctuations of the scalar field give rise to a metric perturbations in the open universe. So, we will consider the evolution of the gauge invariant gravitational potential. First consider the continuous modes [19]. The evolution equation for the gauge invariant gravitational potential Φ is given by

$$\Phi_p'' - \frac{6(1 - e^{2\eta})}{3 - 2\eta}\Phi_p' + \left(p^2 + 5 - \frac{4(3 + e^{2\eta})}{3 - e^{2\eta}}\right)\Phi_p = 0. \tag{94}$$

For small t, Φ_p behaves as $T_{\pm p}(\eta)e^{2\eta}$. For general t, Φ_p behaves as

$$\Phi_p \sim T_{\pm p}(\eta)e^{2\eta}\left(1 - \frac{p \mp i}{3(p \pm i)}e^{2\eta}\right). \tag{95}$$

Furthermore for small t, this metric perturbation is related to the fluctuations of the scalar field by

$$\Phi_p \sim \frac{4\pi G\mu^3}{(\mp ip + 2)H^2}e^{2\eta}\ \delta\phi_p. \tag{96}$$

The initial fluctuations of the scalar field are given in eq.(89). Then, the metric perturbation generated during the second inflation is given by

$$\begin{aligned}
\Phi &= -i\frac{4\pi G\mu^3}{H}\sum_{lm}\int_0^\infty dp\frac{1}{2\sqrt{2p}}Y_{plm}(r, \Omega)\frac{1}{\sqrt{2\sinh \pi p}} \\
&\times \left[\left((e^{\pi p/2}g_1(p, \lambda)\tilde{T}_p(\eta) + e^{-\pi p/2}g_2(p, \lambda)\tilde{T}_{-p}(\eta))\hat{\boldsymbol{a}}_p\right.\right. \\
&+ \left.\left.(e^{-\pi p/2}g_1^*(p, \lambda)\tilde{T}_{-p}(\eta) + e^{\pi p/2}g_2^*(p, \lambda)\tilde{T}_p(\eta))\hat{\boldsymbol{a}}_{-p}\right) + (h.c.)\right],
\end{aligned} \tag{97}$$

where

$$\tilde{T}_{\pm p}(\eta) = T_{\pm p}(\eta)\frac{e^{2\eta}}{\mp ip + 2}\left(1 - \frac{p \mp i}{3(p \pm i)}e^{2\eta}\right). \tag{98}$$

The variable which has a normalization that relates more directly to the density perturbation after reheating is given by $\mathcal{R} = 16\pi G(V^2/V_{,\phi}^2)\Phi$. We define the power spectrum of $\mathcal{R}$ by

$$_{BD}\langle 0|\mathcal{R}(r, \eta)\mathcal{R}(r', \eta)|0\rangle_{BD} = \sum_{lm}\int_0^\infty dp\ Y_{plm}(r)Y_{plm}(r')P_{\mathcal{R}}(p, \eta), \tag{99}$$

where $\hat{\boldsymbol{a}}_p|0\rangle_{BD} = 0$. Taking the limit $\eta \to 0(t \to \infty)$, we obtain

$$\begin{aligned}
P_{\mathcal{R}}(p, \lambda) &= P_{BD}(p) \times \\
&\left[|g_1(p, \lambda)|^2 + |g_2(p, \lambda)|^2 - \frac{1}{\cosh \pi p}\left(\frac{p - i}{p + i}g_1(p, \lambda)g_2^*(p, \lambda) + \frac{p + i}{p - i}g_1^*(p, \lambda)g_2(p, \lambda)\right)\right],
\end{aligned} \tag{100}$$

where

$$P_{BD}(p) = \left(\frac{3H^3}{\mu^3}\right)^2\frac{\coth \pi p}{2p(p^2 + 1)}. \tag{101}$$

The power of the continuous modes in the logarithmic interval p at $p \gg 1$ is given by

$$\lim_{p \to \infty} \frac{p^3}{2\pi^2} P_{\mathcal{R}}(p, \lambda) = \frac{1}{4\pi^2} \left(\frac{3H^3}{\mu^3}\right)^2 \sim \left(\frac{M_*^2}{M_p M}\right)^4 \left(\frac{H}{m_T}\right)^2. \tag{102}$$

Here we use the fact the valley bounce gives the initial condition as $|\phi_* - \varphi_T| \sim M^2/m_T$, then $\mu^3 = m_T M^2$. This quantity should be of the order 10^{-10} from the observation. This can be achieved by taking $(M_*^2/M) \ll M_p$. We show the dependence of λ in $P_{\mathcal{R}}$ in Fig.10.

The discrete modes can be treated in the same way. Φ_Λ generated from $\delta\phi_\Lambda$ is given by

$$\Phi_\Lambda = \sum_{lm} \frac{2\pi G \mu^3 N_\Lambda}{H \Gamma[1 + \Lambda]} \tilde{T}_\Lambda(\eta) Y_{\Lambda lm}(r_R, \Omega), \tag{103}$$

where

$$\tilde{T}_\Lambda = T_\Lambda(\eta) \frac{e^{2\eta}}{\Lambda + 2} \left(1 + \frac{1 - \Lambda}{3(1 + \Lambda)} e^{2\eta}\right). \tag{104}$$

Taking the limit $\eta \to 0$, we obtain the power spectrum of $\mathcal{R}$

$$P_{\mathcal{R}}(\Lambda_i, \lambda) = \left(\frac{3H^3}{\mu^3}\right)^2 \left(\frac{N_{\Lambda_i}(\lambda)}{\Gamma[2 + \Lambda_i(\lambda)]}\right)^2. \tag{105}$$

In some open inflation model, the contribution of the discrete modes gives the strong constraint on the model [23]. The supercurvature mode produces very large scale metric perturbations and enhances the amplitude of the low multipoles of the CMB anisotropies. No evidence for such enhancement in the observed spectrum implies that the contribution of these discrete modes must not dominate the contribution of the continuous modes. Furthermore, if the amplitude of the supercurvature modes is large, the universe is not open but quasi-open beyond the coherent length of the supercurvatuer modes [24]. In our model, however, the last factor in the power spectrum $P_{\mathcal{R}}(\Lambda_i, \lambda)$ is $O(1)$ (see Fig.10), then there is no inconsistency with the observed CMB anisotropies and the universe looks like an infinite open universe described by the valley bounce.

The harmlessness of the supercurvature mode can be deduced from the analysis of the case the CD solution describes the tunneling and the thin-wall approximation can be used. In this case, the supercritical mode is the wall fluctuation mode given by $\delta\phi_w = N_w(\dot{\phi}_{CD})$. Here the normalization constant is given by $N_w = (\int d\sigma a(\sigma) \dot{\phi}_{CD}^2)^{-1/2}$. Within the thin wall approximation, this can be evaluated as $N_w \sim (RS_1)^{-1/2}$, where S_1 is the surface tension of the wall and R is the radius of the bubble. The surface tension of the wall is estimated by $S_1 \sim m_T(\triangle\phi)^2$, where $\triangle\phi$ is the scale of the variation of the field during tunneling. The curvature perturbation generated from this wall fluctuation is given by $\mathcal{R} \sim (H/\dot{\phi}_{CD})\delta\phi_w \sim H/\sqrt{RS_1}$. Using $R \sim 1/H$ and $m_T \sim H$, this can be estimated as $\mathcal{R} \sim H/\triangle\phi$. Thus, the thickness of the barrier the field passes during the tunneling determines the amplitude of the curvature perturbation generated from the wall fluctuation mode. In the case the valley bounce describes the tunneling, the supercritical mode can not be interpreted as the wall fluctuation mode. But the behavior of the supercritical mode resembles that of the wall fluctuation mode. Thus we expect this analysis can be applied. Since the valley bounce gives $\triangle\phi \sim M^2/m_T$, the contribution of the supercritical mode is suppressed. Then, the constraint from the discrete mode is not strong in this model.

6 Conclusion

It is difficult to provide the model which solves the horizon problem and at the same time leads to the open universe in the context of the usual inflationary scenario. In the one bubble open inflationary scenario, the horizon problem is solved by the first inflation and the second inflation creates the universe with the appropriate Ω_0. Many works have been done within this framework of the scenario and it is recognized this scenario requires additional fine-tuning [3, 4]. The defect comes from the fact that the requirement the curvature around the barrier should be larger than the Hubble scale to avoid large fluctuations contradicts to the requirement the curvature of the potential should be small to realize the second inflation inside the bubble. Additional constraint comes from the fluctuations generated in the decay process, which can be observed and reject some models [23].

In this paper we pointed out a possibility of constructing a model without these difficulties by reconsidering the tunneling process. If the curvature around the potential is small, the tunneling is described by one of a family of the almost saddle-point solutions [6]. This is because the true saddle-point solution, that is, the Hawking Moss solution does not satisfy the boundary condition for the false vacuum decay. A family of the almost saddle-point solutions generally forms a valley line in the functional space. We called the configurations on the valley line valley bounces. To identify the valley bounces, we formulated the valley method in the de Sitter spacetime and clarified the structure of the valley bounces. In this method the valley bounces can be identified using the fact the trajectory they form in the functional space corresponds to the line on which the action varies most gently.

Our assumption is that one of the valley bounces describes the creation of the bubble inside of which is our open universe and determines the initial condition in the open universe. Based on this assumption, we found that there occurs the second inflation without the large fluctuations even if the curvature around the barrier is small compared with the Hubble scale.

The fluctuations of the tunneling field give rise to the metric perturbation. These can be observed in our open universe. The fluctuations around the valley bounce which are orthogonal to the gradient of the action are relevant to the observable. We calculated the power spectrum of the metric perturbations generated in the second inflation and found these fluctuations can be compatible with the observations. In some models of the open inflation, the discrete mode of the fluctuations gives strong constraint on the model. We showed this is not the case in our model. Hence, using the valley bounce, we can solve the problem which arises in the open inflationary scenario besides the usual fine-tuning of the inflationary scenario. Then the one bubble open inflation model can be constructed in the simple model with the polynomial form of the potential.

Our conclusion is based on the assumption that an individual valley bounce describes the tunneling and gives the initial condition of the tunneling field in the open universe. Although this assumption seems to be plausible, we note that further investigations are needed for the justification of this assumption.
